This paper was originally prepared as a report for the Australian Department of Education, Employment and Workplace Relations (DEEWR). The views expressed are those of the authors and do not necessarily represent the views of the DEEWR. The authors thank Sheldon Rothman of the Australian Council for Educational Research for providing one set of the school achievement scales used in this paper. He bears no responsibility for our use of those scales. We have benefited from comments from editor David Figlio, an anonymous referee, and seminar participants at the Ministerial Council on Education, Employment, Training and Youth Affairs (MCEETYA) Performance Measurement and Reporting Taskforce and the Queensland Studies Authority Senior Schooling Conference. In revising this report for publication, Susanne Schmidt and Elena Varganova provided outstanding research assistance.

Abstract

Outside the United States (U.S.), very little is known about long-run trends in school productivity. We present new evidence using two data series from Australia, where comparable tests are available back to the 1960s. For young teenagers (aged 13-14), we find a small but statistically significant fall in numeracy over the period 1964-2003, and in both literacy and numeracy over the period 1975-1998. The decline is in the order of one-tenth to one-fifth of a standard deviation. Adjusting this decline for changes in student demographics does not affect this conclusion; if anything, the decline appears to be more acute. The available evidence also suggests that any changes in student attitudes, school violence, and television viewing are unlikely to have had a major impact on test scores. Real per-child school expenditure increased substantially over this period, implying a fall in school productivity. Although we cannot account for all the phenomena that might have affected school productivity, we identify a number of plausible explanations.

Keywords: education production function, literacy, numeracy

I. Introduction

All too frequently, education policy debates focus on inputs rather than outputs. To a large extent, this is a function of the available data. While input measures such as class sizes, teacher salaries, and per-student funding are readily comparable over time, output measures such as test scores are often not designed to be compared across years (either because they are re-standardized each time they are administered, or because the test instrument itself is changed from year to year).

Yet from a policymaking perspective, what should matter most is school productivity – the results a school system is achieving for a given level of inputs. As with other productivity measures in the economy, it is reasonable to expect that these should steadily improve over time, as new innovations allow schools to produce better results with the same level of real inputs.

In this paper, we analyze long-run trends in school productivity in Australia, comparing standardized test score results in literacy and numeracy with data on per-student expenditure. Combining data from two nationally representative sets of tests, we are able to compare numeracy scores from 1964 to 2003, and literacy scores from 1975 to 1998.

Although literacy and numeracy scores are by no means the sole output of the education process, equipping children with good reading, writing, and mathematical skills is nonetheless an important function of schools. At an individual level, studies have shown that Australian students with better literacy and numeracy in their early teenage years are more likely to be employed when aged in their twenties (Marks and Fleming 1998a), and that conditional on being employed, they tend to earn higher wages (Marks and Fleming 1998b). At a national level, countries where the labor force is more numerate tend to grow faster than countries with lower levels of numeracy (Hanushek and Kimko 2000; Jamison, Jamison, and Hanushek 2006).

Only a small number of studies has looked at changes in test scores and spending over several decades. For the U.S., Hanushek (1997) showed that test scores were essentially flat over the period 1970-94, while real per-child expenditure grew by 2.5 to 3 percent per year. Hoxby (2001) demonstrated that this finding held true for the period 1970-98, and that adjusting for student demographics made little difference to the overall pattern. Similarly, Gundlach, Woessmann, and Gmelin (2001) find that test scores in 11 developed countries were basically flat over the period 1970-94, while real per-child funding rose dramatically. However, since their findings rely on benchmarking against the U.S. National Assessment of Educational Progress (NAEP), these results are partly driven by trends in U.S. NAEP scores.

Our analysis of school productivity follows an extensive literature on public sector productivity (see e.g. Rosen 1993; Atkinson 2005; Boyle 2006; Douglas 2006; Weale 2007). As Atkinson (2005, p. 18) noted, “There is a strong case for devoting significant resources at this time to improving the measurement of public sector output on account of its increased saliency in policymaking and public debate”. However, as Rosen (1993) has pointed out, one hesitation that arises when assessing public sector productivity is choosing the appropriate measure. Since no metric perfectly captures all aspects of the effectiveness of a public sector organization, it is important to recognize that any chosen output measure is merely a proxy variable.

Notwithstanding their limitations, studies that have analyzed educational productivity have typically opted to use test scores as their primary output measure (see e.g. Atkinson 2005). For example, the United Kingdom (UK) Department for Education and Skills (2005) noted that it had considered other output measures, such as school inspections, but concluded that test scores were preferable on the basis of data availability, transparency, and their potential to be linked to labor market outcomes. The Australian Productivity Commission (SCRGSP 2007) lists its preferred outcome measures as test scores for reading, writing, numeracy, science, and civics; plus technological literacy, vocational education in schools, completion, destination, and “other areas to be identified”.¹

So far as we are aware, ours is the first study to look at long-run trends in literacy and numeracy without relying on the U.S. NAEP. For U.S. policymakers, Australia is a useful laboratory in which to consider changes in school performance, since while its labor market has much in common with the U.S. labor market, its school system has a number of features that distinguish it from the U.S. Chief among these are that schools are funded by the federal and state governments (and not by local property taxes); that around one-third of pupils attend non-government schools; and that decisions about teacher appointment and remuneration in government schools are made at a state level.

To preview our results, we find no evidence that test scores have risen over the past four decades, and some evidence that scores have fallen. This finding is consistent with earlier studies using some of the same datasets (Afrassa and Keeves 1999; Rothman 2002). We explain how this finding can be reconciled with evidence on the ‘Flynn Effect’ (growth in measured intelligence quotient (IQ) scores over the twentieth century in developed countries), and with Australia’s ranking on international tests. We also find that adjusting for the observed demographic characteristics of students does not affect this conclusion; if anything, the decline appears to be more acute. We also review other possible explanations, such as changes in early school leaving behavior, and conclude that they are unlikely to have significantly affected trends in test scores.

Turning to education expenditure, we observe a significant increase in per-child spending from the mid-1960s to the early 2000s. If we measure school productivity in terms of the average test score divided by the average real per-child expenditure, this implies that school productivity has fallen over the past four decades. Using our preferred measure of school input prices, we estimate that school productivity has declined by 12-13 percent between 1975 and 1998, and by 73 percent between 1964 and 2003.

The remainder of this paper is structured as follows. Section II outlines the test scores that we use, and presents the basic trends in literacy and numeracy. Section III examines the extent to

¹ Our analysis does not use school completion rates as a metric of school quality, on the basis that students’ decisions to obtain more schooling do not necessarily reflect higher school productivity. In the Australian context, youth labor market conditions have been shown to be extremely important. Ryan and Watson (2004) noted that the parameters of the regression equation they estimated, in conjunction with the change in variable values, would have attributed the entire increase in Australian Year 12 retention rates from the 1970s to the 1990s to the decline in full-time job opportunities for teenagers.

which the observed patterns might be due to changes in demographics, or other factors beyond the school gate. Section IV looks at how per-child spending has changed. The final section concludes.

II. Trends in Literacy and Numeracy

Longitudinal Surveys of Australian Youth

The first set of tests that we use to analyze changes in literacy and numeracy are data from four Longitudinal Surveys of Australian Youth (LSAY) cohorts. These cohorts are the Youth in Transition 1961 and 1975 birth cohorts (YIT 61 and YIT 75) and the Longitudinal Surveys of Australian Youth 1995 and 1998 Grade 9 cohorts (LSAY 95 and LSAY 98). Those in the first cohort sat the literacy and numeracy tests in 1975, while those in the last cohort sat the tests in 1998. Although subsequent cohorts of the LSAY have been surveyed, the test instrument is not comparable to that used in earlier cohorts, and changes to the survey design mean that the subjects in the later cohorts are older.

Students in the first two LSAY cohorts sat standardized tests at age 14, while students in the last two cohorts sat standardized tests in grade 9. There are four ways to compare achievement across time using these data: by using the full sample in all years, by restricting the sample to 14 year-olds, by restricting the sample to year 9 students, or by restricting the sample to those who were aged 14 and in year 9.

We adopt the last approach. That is, we opt to compare cohorts by focusing only on the common group: those who were aged 14 and in grade 9. This is designed to limit the impact of changes in the age-grade composition of the surveys over time, since both students' ages and grades may affect their performance on achievement tests.

This is a different approach from the preferred specification used by Rothman (2002), who argues that using those aged 14 and in grade 9 suffers from the problem that underperforming students were more commonly required to repeat grades in the 1970s than in the 1990s. Rothman cites Australian Bureau of Statistics (ABS) data showing that the share of 14 year-olds who were enrolled in grade 8 or below fell from 24 percent in 1975 to 16 percent in 1995-2000, and argues the average quality of the pool of students aged 14 and in year 9 might have been lower in the later cohorts. Therefore, average school achievement for students aged 14 and in year 9 in the later cohorts would be expected to be lower than in earlier cohorts.

Our view is that any change in grade repetition is unlikely to have had a significant impact on trends in the LSAY. First, there were offsetting trends on age-grade distributions across states and territories. Grade repetition rates certainly fell over the period in states and territories where they were high initially. But in other states and territories, there were trends towards later school commencement, especially among those who would have been youngest in their grade cohorts, and once more this phenomenon might be expected to have affected students who were of below-average ability. Thus in some states and territories, the proportion of students 'old' for their grade, given the school commencement rules operating in their jurisdiction, actually

increased in the later LSAY cohorts, presumably raising the average ability of 14 year-olds in grade 9. There were also some states and territories in which these patterns barely changed at all.

Second, empirically, the shares of the cohorts aged 14 and in year 9 did not change as much in the LSAY data as it did in the ABS data. The (weighted) proportion of the sample aged 14 and in year 9 was 60.3 percent in the YIT 61 cohort and 63.7 percent in the LSAY 98 cohort. In unweighted data, the change was just 1.5 percentage points. The reason the change in the proportions is smaller in the LSAY data is one of coverage – students’ integer ages in LSAY were recorded as of the 1st of October in the survey year, and in the YIT surveys only those aged 14 as of that date were included in the surveys. In the ABS data, ages are classified as of the 1st of July. Because of the complex pattern in which students born at different times of the year are distributed across school grades, which also differs substantially by jurisdiction, this different coverage means that the LSAY data have been much less affected by the trend identified by Rothman (2002) (and by compositional effects driven by differential population growth between states) than the ABS data.

Finally, it is possible to estimate how much such phenomena might have affected our results. First, we can identify students aged 14 and in year 9 who should come from similar parts of the ability distribution in the different cohorts. These are individuals born in the same months of the year from the same state, but in different cohorts, where the proportion of the sample aged 14 and in year 9 was the same. It is also possible to identify cohorts of students where the distribution changed substantially in the way identified by Rothman (2002), that is, where the proportion aged 14 and in year 9 increased. We find the trends we present below for the entire group aged 14 and in year 9 are also borne out for these other groups, but the decline in literacy and numeracy performance is most pronounced in the group where the proportion aged 14 and in year 9 increased the most – which is precisely the effect identified by Rothman (2002).²

The LSAY literacy and numeracy scales used here are taken from Rothman (2002). They were developed using the common items asked of the cohorts using a Rasch item response model. The scales were constructed to have a mean of 50 and a standard deviation of 10 across the cohorts.

Figures 1 and 2 contain trends in test scores from the LSAY, with dots representing the mean, and error bars representing the 95 percent confidence interval for the mean. Across all tests, the mean of the standardized test scores is set at 50 and the standard deviation at 10. The results show that over the period 1975-98, there was a statistically significant decline in the literacy and numeracy test scores of both boys and girls.³

Was the fall in mean scores driven mostly by changes in the left tail or right tail of the distribution? And how did the distribution of test scores across schools change over time? To

² Moreover, the trends are identical where we also exclude individuals who appear ‘old’ or ‘young’ for their grade given the typical age-grade level of other students in their state born in the same months of the year.

³ This finding is sensitive to our choice of students aged 14 in year 9. Results presented in Rothman (2002) show that when the comparison uses the full sample, or just 14 year-olds, literacy and numeracy scores are flat from 1975-98.

answer these questions, Figure 3 presents kernel density plots (effectively smoothed histograms) of the distributions in 1975 and 1998. In these graphs, the horizontal axis shows the standardized score, while the vertical axis shows the share of observations that are at or close to each score. Panels A and B show the distribution of individual literacy and numeracy scores. In the case of individual literacy scores, it appears that the distribution has simply moved towards the left. By contrast, the distribution of individual numeracy scores has also changed shape slightly, with fewer children scoring around 60, and more scoring just below 50.

Panels C and D show the distribution of average literacy and numeracy scores at the school level. In both cases, the graphs overlap on the far right tail, indicating a similar number of high-performing schools in both years. Elsewhere, the graphs appear to have essentially shifted to the left. For literacy, the distribution of school performance has become slightly more dispersed over time; while for numeracy, the distribution of performance across schools has become slightly more compressed over time.

IEA Surveys

The second source of data that we analyze are five mathematics surveys conducted by the International Association for the Evaluation of Educational Achievement (IEA). These are the 1964 First IEA Mathematics Study, the 1978 Second IEA Mathematics Study, the 1994 Third IEA Mathematics Study (also known as the 1995 Third International Mathematics and Science Study, or TIMSS, though it was conducted in Australia in 1994), the 1999 TIMSS, and the 2003 TIMSS.

In comparing the cohorts, we need to take into account shifts in the composition of test-takers. There are three aspects to this. First, the geographic coverage of the test steadily increased over time, with the 1964 survey covering five states (New South Wales - NSW, Victoria - VIC, Queensland - QLD, Western Australia - WA, and Tasmania - TAS), the 1978 survey covering these plus the Australian Capital Territory (ACT) and South Australia (SA), and the 1994 and subsequent surveys also covering the Northern Territory (NT).⁴ Second, the surveys extended their coverage across school types, with the 1964 survey covering only government schools, and later surveys covering both government and non-government schools. And third, the surveys changed their age-grade coverage, with the 1964 survey covering grade 8, the 1978 survey covering 13 year-olds, the 1994 survey covering grade 7-9, the 1999 survey covering grade 8-9, and the 2003 survey covering grade 8.

To take account of these various shifts, we use a Rasch item response model to estimate a standardized score, using common questions across the tests.⁵ For ease of comparison, we then

⁴ Although the ACT was part of the NSW schooling system in 1964, ACT schools do not appear to have been sampled in the 1964 survey (Afrassa and Keeves 1999).

⁵ The Rasch item response model is used to create a standardized score for the 1964, 1978, and 1994 tests. However, not all the common items in the 1964-94 tests also appear in the 1999 and 2003 tests. We therefore take advantage of the fact that for the 1994-2003 tests, the IEA has already created a variable called “National Math Rasch Score”. We standardize this variable so that in 1994, it has the same mean and standard deviation as the Rasch score derived from common items in the 1964-94 tests.

express the tests on the same scale as the LSAY results (with a mean of 50 and a standard deviation of 10). Where T is the test score of student i , tested in year y , in grade g , and of age a , we estimate the following regression:

$$T_{iyga} = \alpha + \beta_y I^{\text{test year}}_y + \gamma_g I^{\text{student grade}}_g + \delta_a I^{\text{student age}}_a + \varepsilon_{iyga} \quad (1)$$

The parameter β_y denotes how mean scores have changed, holding constant changes in the age and grade composition of students taking the test.⁶ Since the version of the 1994-2003 datasets that we are using does not contain information on state, nor on whether the student attended a non-government or government school, we first estimate the model just for 1964 and 1978, with the sample restricted to the student population covered by the 1964 test. We observe a decline of 2.5 points, which is significant at the 1 percent level. We then estimate the model using data for all tests, and find that the drop from 1964 to 1978 is 2.0 points (still significant at the 1 percent level). Given the similarity between these two estimates, we opt to compare across all cohorts.

Figure 3 charts the results. Over the 39 years from 1964 to 2003, we observe a statistically significant decline in test scores, with the typical student scoring 1.1 points lower in 2003 than in 1964 (significant at the 5 percent level). When we analyze boys and girls separately, the drop is of similar magnitude for each group, and statistically significant at the 10 percent level. Rescaling the scores to a common scale, the mean scores (for boys and girls combined) were 51.4 in 1964, 49.3 in 1978, 51.6 in 1994, and 50.2 in both 1999 and 2003. In 1999, the most recent year that the IEA surveys covered multiple grades, students' mathematics scores rose by an average of 4 points per grade. These findings therefore imply that the numeracy of the typical young teenage student in 2003 was approximately a quarter of a grade level behind his or her counterpart in 1964.

Although we use a somewhat different methodology, our results from 1964 to 1978 are close to those of Afrassa and Keeves (1999), who find a decline of approximately half a year of mathematics learning between 1964 and 1978. However, while Afrassa and Keeves find a decline of approximately one year of mathematics learning between 1964 and 1994, we observe

⁶ On the face of it, this approach differs from that used to analyze the LSAY data. If we estimate the equivalent of equation (1) with LSAY data using all observations with student age, grade, school sector, and state controls, the declines between the first and last cohorts for all students are 1.7 and 1.2 points for literacy and numeracy respectively; smaller but close to the estimates in Figures 1 and 2. These declines were statistically significant at the 1 percent level. The alternative methodologies do not produce results that differ qualitatively. Where we also address the potential endogeneity of age and grade in the equation using LSAY data (which is another way of characterizing Rothman's argument for using the whole Year 9 cohort), the results do not change in any qualitative way. We use as instruments for age and grade the student's birth month and its interaction with school commencement rules. These rules, which vary between jurisdictions and changed over time, largely determine students' ages and grades when surveyed in the LSAY cohorts. The declines in performance between the first and last surveys were 1.4 and 0.8 points for literacy and numeracy, respectively, with the former significant at the 1 percent level and the latter at the 5 percent level.

no change in scores over this period. This is most likely due to the fact that our results adjust for both age and grade effects, while Afrassa and Keeves only adjust for grade effects.

To see whether the fall in mean scores was driven by changes in particular points of the distribution (either across individuals or across schools), Figure 5 presents kernel density plots of the distributions in 1964 and 2003. As with the LSAY density functions, the horizontal axis shows the standardized score, while the vertical axis shows the share of observations that are at or close to each score. Panel A shows the distribution of individual numeracy scores – indicating that the distribution has simply moved towards the left, with little change in dispersion. Panel B shows the distribution of average numeracy scores at the school level, with the distribution shifting to the left over time. In addition, there appears to be greater school-level dispersion. However, the apparent change in dispersion is probably mostly due to changes in the sampling frame. While the 2003 IEA test sampled schools across the nation, the 1964 test only included government schools in five states. The omission of non-government schools from the earlier test is the most likely reason why the school-level distribution appears narrower in 1964 than in 2003.

Recent Evidence – Has There Been a Turnaround?

Although our main results are based upon the LSAY and IEA surveys, it is worth briefly noting the available evidence on trends in literacy and numeracy in Australia during the 1990s and 2000s. Reports by the state auditor-general’s offices in New South Wales and Victoria (Australia’s two largest states) found little change in literacy and numeracy scores over the periods 1996-2007 and 1998-2007 respectively (NSW Audit Office 2008; Victorian Auditor-General 2009). The Programme for International Student Assessment (PISA 2007) provides comparable data on reading over the period 2000-2006, and mathematics over the period 2003-2006. According to PISA, the reading performance of Australian 15 year-olds fell from 2000 to 2006 (a statistically significant drop), and the mathematics scores of Australian 15 year-olds fell from 2003 to 2006 (statistically insignificant). The other comparable survey is the Adult Literacy and Life Skills Survey (ABS 2007), which found that the document literacy and prose literacy of 15-19 year-olds fell slightly from 1996 to 2006 (though not by a statistically significant margin). Over the same period, document and prose literacy in the general population rose slightly.

Other Evidence – Flynn Findings

In addition, it is worth mentioning other sources of data on the cognitive abilities of Australian children which may (at least initially) appear to contradict the results presented here. The first is the well-known ‘Flynn Effect’, under which IQ scores in many developed nations have shown an increase during the twentieth century (Flynn 1987, 2006). If the test scores of young teenagers are stagnant, how can it be the case that IQ scores are rising in the general population?

There are three answers to this. First, in the case of Australia, Flynn’s data are drawn from an earlier era. Table 1 juxtaposes Flynn’s results with those shown above. We follow Flynn in converting the LSAY and International Mathematics tests into the IQ scale (with a mean of 100 and a standard deviation of 15). While Flynn (1987) demonstrated that Australian test scores grew by 0.4 to 0.5 points per year in the interwar period and the immediate post-war decades, the

data shown above indicate that the last three decades of the twentieth century saw a slight decline in test scores.⁷

The second point to be made about Flynn's findings is that – across a wide range of countries – they appear to be more robust when tests are administered to adults rather than to younger children. Flynn (1987) presents 'strong data' on test score gains for seven countries. In five of these countries, the data are for adult subjects. As he acknowledges, one factor that might be driving higher test scores among the adult population is higher school completion rates, and rising rates of post-secondary education. Even if test scores of schoolchildren were flat, more years of education might be expected to boost adult test scores.

The third factor to bear in mind when reconciling Flynn's findings with those presented here is that the Flynn effect is largest for standard IQ tests (such as the Ravens, Stanford-Binet, and Wechsler tests), and virtually absent for curriculum-based tests. Discussing evidence for the U.S. and other developed countries, Flynn (1999, p. 8) noted that long-run test score gains are "small to nil on achievement tests. That is to say, they fall away the closer we come to the content of school-taught subjects". Indeed, Flynn (2009) presented evidence that in Britain, test scores for children aged 14-15 declined slightly over the period 1980-2008.

Together, these three factors – different time periods, different ages, and different types of tests – suggest that the absence of a discernable increase in Australian test scores of young teenagers on a curriculum-based test is readily reconcilable with the available evidence on the Flynn effect.

Other Evidence – International Comparisons

The other piece of evidence that may (to some eyes) appear to contradict the long-run trends is the fact that Australia ranks highly when compared with other developed countries. Pooling data for three international tests: the 1995, 1999, and 2003 TIMSS tests, the 2000 and 2003 PISA tests, and the 1994-8 International Adult Literacy Survey (IALS), Brown et al. (2005) compare rankings for a group of 18 OECD countries.⁸ This comparison has the advantage that all of the countries are of a similarly high income level (on a purchasing power parity basis, Australia's Gross Domestic Product (GDP) per capita is ranked 9th among these 18 countries).

Pooling these data sources, Brown et al. find that the ranking of the median Australian respondent is, on average, 6.6 out of 18, indicating that the literacy, numeracy, and scientific knowledge of young Australians is somewhat above the OECD average. For PISA reading and for TIMSS and PISA mathematics, the typical Australian student is two-thirds to three-quarters of a standard deviation above the OECD mean. For PISA science and TIMSS science, the typical

⁷ See also de Lemos (1997), who discusses evidence on changes in Australian students' test scores from the 1950s to the 1990s. One contrary study is Nettlebeck and Wilson (2004), who found that the Peabody Picture Vocabulary Test scores of a small sample of Australian school children rose between 1981 and 2001. However, both of their samples are drawn from a single primary school, making it quite possible that the observed changes were due to local demographic shifts, and were not nationally representative.

⁸ Although IALS covers the entire adult population, Brown et al. (2005) only analyze respondents aged 16-24.

Australian student is nearly a full standard deviation above the OECD mean, and for the IALS literacy tests, the typical Australian student is at or slightly below the OECD mean.

Just as a rich country can experience a period of no economic growth (yet still remain better off than many other countries), so Australia's above-average ranking on international tests can easily be reconciled with the failure of test scores to rise over recent decades. Countries that rank reasonably well in international comparisons are not necessarily also improving over time. Indeed, the findings of Gundlach, Woessmann, and Gmelin (2001) indicate that test scores in OECD countries were essentially flat over the period 1970-94. It is therefore unsurprising that the failure of Australian test scores to rise has not dragged the nation to the bottom of the international league tables.

III. Alternative Explanations

In this section, we canvass four possible explanations for the fact that test scores have not risen over time. Perhaps student demographics have changed in such a way that we would have expected the more recent cohort of students to underperform earlier cohorts? Maybe social factors such as bullying and television viewing have made children harder to teach? Perhaps lower-ability students dropped out of school in the 1960s and 1970s? Or maybe those literacy and numeracy questions which are comparable over time are the most irrelevant to the modern labor market?

Demographic Shifts

One plausible explanation for the decline in test scores over time is that the demographic characteristics of students have changed in such a way as to affect test scores. For example, it tends to be the case that students from a language background other than English do worse on literacy and numeracy tests (see e.g. Rothman 2002). Since the share of students has risen over time, this would be expected to reduce the average test scores. Conversely, it tends to be the case that students with university-educated parents do better on literacy and numeracy tests (see e.g. Cardak and Ryan 2006). Since the share of students with university-educated parents has risen over time, this would be expected to raise average test scores. Thus the overall effect of changing demographics is ambiguous.

To separate the effect of changing demographics, we employ a technique known as Oaxaca decomposition (Oaxaca 1973). Although traditionally used to decompose gender and racial pay differences, Oaxaca decompositions have also been employed to look at test scores (see e.g. Cook and Evans 2000). In the present case, such a decomposition allows us to separate the change in test scores into three components: changing attributes of the student body, changing returns to these attributes, and shifts that are not explained by demographics. However, it is important to note that such an exercise is limited by the fact that our datasets do not contain a comprehensive set of demographic characteristics. We return to this issue below.

In the case of comparing LSAY test scores from 1975 and 1998, the Oaxaca decomposition involves estimating the following regressions, where t denotes the test score, Z_j is a vector of student demographics, α is a constant, β_j are estimated parameters, and ε is a normally distributed

mean-zero error term. Subscript i indexes individuals, j indexes demographics, and 75 and 98 denote the 1975 and 1998 tests respectively.

$$\begin{aligned} t_{i75} &= \alpha_{75} + \beta_{j75} Z_{ij75} + \varepsilon_{i75} \\ t_{i98} &= \alpha_{98} + \beta_{j98} Z_{ij98} + \varepsilon_{i98} \end{aligned}$$

Denoting mean scores in 1975 and 1998 as T_{75} and T_{98} respectively, the change in mean test scores can be written as:

$$\Delta T = T_{98} - T_{75} = (\alpha_{98} + \beta_{j98} Z_{j98}) - (\alpha_{75} + \beta_{j75} Z_{j75})$$

Equivalently,

$$\Delta T = \beta_{j98}(Z_{j98} - Z_{j75}) + Z_{j75}(\beta_{j98} - \beta_{j75}) + (\alpha_{98} - \alpha_{75}) \quad (2)$$

The first term on the right side of equation (2) is the change in test scores that can be attributed to shifts in student demographics; the second term is the component due to changes in the coefficients on those demographics, and the third term is the component that cannot be explained by demographics or coefficients.

To see this more precisely, note that if student demographics are exactly the same in 1975 and 1998, then the first term should be zero. If the returns to student demographics are exactly the same in 1975 and 1998, then the second term should be zero. And if the change from 1975 to 1998 is entirely explained by changes in demographics and the returns to those demographics, then the third term should be zero.

In addition, it is important to note that the effects need not go in the same direction. That is, it is perfectly possible for the returns to student demographics to contribute to a rise in test scores, and for an unexplained component to contribute to a fall in test scores.

Table 2 presents results. Among the sample of students for whom we have non-missing demographic characteristics in the LSAY, the decline in test scores from 1975 to 1998 is only around half as large as across the full population (-1 point for literacy, and -0.6 points for numeracy).⁹ However, when we decompose the change, we find that shifts in demographic

⁹ The main reason for missing demographics in the LSAY is that a number of the relevant questions were not asked in the first wave. For example, we drop almost 20 percent of observations in the LSAY 1975 cohort (principally because questions on parental occupations were not asked until 1978), and 36 percent of observations in the LSAY 1998 cohort (principally because the question about siblings was not asked until 2000). To see how this might have affected our analysis, we focus on the dropped cases (those with some missing demographics), and check how the key demographic patterns in these cases shifted over time. We observe a similar pattern to that seen in Table 2: among the dropped cases, there are increases in parental education levels, in the proportion of students from non-English-speaking backgrounds, and in the proportion attending private schools. This suggests that dropping cases with missing demographics is unlikely to have significantly biased the LSAY analysis in Table 2. (Unfortunately, we cannot carry out a similar robustness check for the IEA, since that analysis

characteristics should have acted to increase test scores over time. Taking account of shifts in the levels of and returns to student demographics, the decline in test scores is considerably larger: around 3.4 points for literacy and 3.9 points for numeracy.

For the IEA test, our approach is very similar, except that because the age and grade coverage of the test changes over time, we take as the dependent variable the residual from a regression of the student's test score on indicator variables for age and grade. This can be thought of as parsing out differences in test coverage. The Oaxaca decomposition then compares the 1964 and 2003 test cohorts. Among the sample of students for whom we have non-missing demographic characteristics in the IEA, the decline in test scores from 1964 to 2003 is similar to the decline in the full sample. When we decompose the shift, we find that shifts in demographic characteristics should have acted to increase test scores over time. Taking account of shifts in the levels of and returns to student demographics, the decline in test scores is 7.6 points. However, this is partly a function of the very limited demographic characteristics available in the IEA tests. If we had the same demographic variables in the IEA as we have for the LSAY, we expect that the adjusted decline in test scores would be smaller than 7.6 points.

In interpreting the results of this decomposition, it is important to note that in both datasets the demographic variables available to us are less extensive than one might like. In particular, we lack precise information on whether the child is in a single-parent family, and our data on neighborhood characteristics are not as precise as would be ideal.¹⁰

Social Trends

Another plausible explanation for the failure of test scores to rise over time is that major social trends adversely affected the school performance of Australian children. For example, if school violence and bullying had prevented students from learning, or television viewing had undercut children's ability to study at home, then it is possible that such factors might have masked an underlying rise in school productivity. In theory, the effect of such social trends would be analogous to the impact of changing demographics, except that the offsetting factors considered here are behavioral and technological rather than demographic.

One possible social factor that might have lowered test scores is if there had been an exogenous increase in violence in schools. Such an increase would have made the job of schools more difficult, potentially counteracting other factors that would have caused scores to rise. To test this, we would ideally have liked comparable data on school-related violence, which were unaffected by changes in punishment regimes. While we were unable to obtain such data, our analysis of the literature on youth crime rates in Australia suggests that violent and property crime rates have stayed constant through the 1980s, 1990s, and 2000s (see e.g. Wundersitz 1993,

focuses principally on parental education, which is missing for about 44 percent of cases in the 1964 survey and about 38 percent of cases in the 2003 survey.)

¹⁰ When analyzing the impact of social trends (e.g. television viewing), we use only data from the 2003 IEA dataset to place an upper bound on the impact of these factors. In theory, such an approach could also have been used to put a bound on the impact of parental employment or family structure, but these demographic variables are unfortunately not available in the 2003 IEA.

2005; Carcach 1997; AIHW 2007).¹¹ It therefore seems unlikely that school-related violence has increased markedly over this period.

Another possibility is that rising television viewing by children made the job of schools more difficult. This could occur either because television viewing crowded out time that would have otherwise been spent doing homework, or because children who watch more television have a shorter attention span.¹² The only survey of children's television viewing habits that we have been able to locate for the 1960s is a 1960 survey of Perth households, which found that children watched an average of 1 hour per day.¹³ By contrast, IEA data for 2003 suggest that children watched around 2 hours of television per day. This extra hour per day of television viewing could plausibly have had an adverse impact on test scores.

A third social factor that might have affected test scores is attitudes to learning. Anecdotally, teachers sometimes report that the current cohort of children is more difficult to teach than cohorts from the 1960s and 1970s. It is sometimes said that children are now less inclined to appreciate school as a learning environment than they were in the past.

Although we do not have comparable data on these social measures in the early test score instruments, proxies for some of them appear in the 2003 IEA survey. Therefore, one way to put bounds on the impact of these social trends is to look at our most recent IEA survey, and – assuming that the 2003 coefficients can be applied to other periods – to see how much a worsening in these variables could have affected test score trends.

For simplicity, we restrict our analysis to three variables: whether the student agrees with the statement “I like being in school”, whether the student says that in the past month “I was hit or hurt by other student(s) (e.g. shoving, hitting, kicking)”, and the number of hours of television and videos that the student watches on a normal school day.

Table 3 shows the results of this exercise. Without parental demographics, students who like school score 2 points higher (statistically significant), students who are bullied score 0.3 points lower (not statistically significant), and an additional hour of television watching is associated with test scores that are 0.8 points lower (statistically significant). These are relatively small effects, given that the standard deviation is 10 points. Including parental demographics in the regression reduces the magnitude of all three coefficients.

These results allow us to predict the impact on scores if (a) every child likes school, (b) no children are bullied, (c) no children watch television at home, and (d) all of the above. It is

¹¹ Wallace (1986) finds a rise in homicides by offenders aged 15-19 between 1958-67 and 1968-81. However, this is partly explained by the higher share of the population in this age band in the latter period.

¹² Using a convincing empirical strategy arising from the quasi-random rollout of television across the U.S., Gentzkow and Shapiro (2008) find no evidence that early exposure to television affected children's subsequent test scores.

¹³ Carter (2005) found that in a sample of 203 Perth children, 86 had a television in the home. Among those with a television in the home, the average daily viewing was 2 hours and 18 minutes, making the mean television viewing time across all children about 1 hour per day.

difficult to imagine that any of these are in fact an accurate characterization of Australian school children in 1964 (as noted above, one study found that children watched an average of 1 hour of television per day in 1960). Yet their combined effect is still only in the order of 1–2 points (0.1–0.2 standard deviations), which is barely more than the observed drop in IEA test scores from 1964 to 2003. At most, these three social factors could account for the decline in IEA test scores, but not their failure to rise.

Just as the demographic analysis in the previous sub-section has its limits, it is also worth acknowledging that this exercise cannot fully reject the possibility that social trends affected Australian test scores. For example, because the 2003 IEA dataset does not contain questions about a child's diet, we cannot test the impact of changing nutrition on test scores. It is also possible that social factors affect test scores in another way than we have modeled; for example, in a highly non-linear fashion, with strong interaction effects, or with important differential impacts across regions or schooling sectors.

Early School Leaving

One plausible explanation for the failure of test scores to rise over time is the possibility that in our earliest cohorts, a significant number of students dropped out of school before the test was conducted. Assuming school leavers would have scored below average on the test, reduced rates of school leaving would lead to a decline in test scores. However, note that if all students obeyed the compulsory school-leaving laws, this should not have occurred. In the 1964 IEA, most students were 13 years old, an age at which Australian children were required to attend school in all states and territories. In the 1975 LSAY, all students were 14 years old, again an age at which Australian children were required to attend school in all parts of the country.

To test whether students actually complied with the school leaving laws, we checked official statistics on the enrolment of the cohort that were to be 13 year-olds in 1964 (using the *Australian Yearbook* for various years). If early dropout was a problem, one would expect to see that the school enrolment of this cohort was larger in prior years. However, we observe little evidence of this. By comparison with the cohort of 13 year-olds in 1964, the cohort of 12 year-olds in 1963 was 0.14 percent larger, the cohort of 11 year-olds in 1962 was 0.02 percent larger, and the cohort of 10 year-olds in 1961 was actually 0.32 percent smaller. This kind of trivial variation suggests that in the early 1960s, very few children dropped out of school between their 10th and 13th birthdays.¹⁴

We conducted a similar exercise on the first LSAY cohort, comparing prior years' enrolment with the age cohort who were to turn 14 in 1975 (unfortunately, we were not able to obtain

¹⁴ Three other factors affecting this calculation are immigration, emigration, and death. The average net immigration rate (inflows minus outflows) was 0.75 percent in 1961-64 and 0.49 percent in 1971-75. In both periods, young teenagers were probably underrepresented in population movements. The annual probability of death for a person aged 10-15 in the 1960s and 1970s was around 0.03-0.04 percent. Both sets of figures indicate that these factors are unlikely to make a significant difference to our results.

enrolment statistics for 1974).¹⁵ By comparison with 14 year-olds in 1975, we found that the cohort of 12 year-olds in 1973 was 1.26 percent smaller, the cohort of 11 year-olds in 1972 was 1.27 percent smaller, and the cohort of 10 year-olds in 1971 was 0.68 percent smaller. This implies that in the early 1970s, about 1 percent of children dropped out of school between their 10th and 14th birthdays. To see the largest effect that this attrition could have had on the mean test scores, suppose that those who dropped out of school would have scored a full standard deviation lower than those who remained. If the mean score of those who stayed had been 50, this implies that the true mean score would have been 49.9. Such variation would have had virtually no effect on the observed results.

Have 1960s and 1970s Questions Become Irrelevant?

Another alternative explanation for the observed changes is that the questions asked in earlier years are simply irrelevant today. For example, if it were the case that literacy questions in the mid-1970s required a knowledge of words that had fallen out of common usage by the 1990s, or if mathematics questions in the mid-1960s required a level of mental arithmetic that many would judge to be unnecessary in the early 2000s, one might wonder whether it was reasonably possible to compare performance on the two tests.

Although there is not a comprehensive way to address this critique, one straightforward approach is to look at the tests themselves. Appendix 1 presents several examples of questions that were common across IEA tests. In our view, these common questions are reasonably representative of modern-day mathematics tests, although they are all computational rather than conceptual. It is therefore possible that the IEA comparison placed more emphasis on computational skills.

Marks and Ainley (1997) analyzed responses to the tests conducted in 1975 and 1995 as part of the LSAY series and found that there were counteracting tendencies in both the literacy and numeracy tests. For the literacy tests, the report found students in the later cohort were more likely to answer correctly questions relating to newspaper articles, but were less likely to answer questions dealing with more difficult textual passages correctly. For the numeracy tests, Marks and Ainley found that students' performance was poorer on computational items in the later cohort, but had improved on conceptual items.

¹⁵ To see whether the absence of 1974 enrolment data affected the results (and to avoid potential problems created by combining enrolment data from different data sources), we replicated the analysis using data from New South Wales (NSW), Australia's largest state. All data were obtained from the annual state yearbooks. By comparison with 14 year-olds in 1975, we found that the cohort of 13 year-olds in 1974 was 1.05 percent smaller, the cohort of 12 year-olds in 1973 was 2.29 percent smaller, the cohort of 11 year-olds in 1972 was 2.48 percent smaller, and the cohort of 10 year-olds in 1971 was 2.50 percent smaller. This implies that in the early 1970s, about 2 percent of children in NSW dropped out of school between their 10th and 14th birthdays. Supposing that NSW dropouts would have scored one standard deviation below average, this would have biased the true result upwards from 49.8 to 50.0.

IV. Expenditure Trends

In Australia, we have been unable to find a consistent series of school expenditure covering the period since 1964.¹⁶ We therefore combine a number of different data sources to produce a consistent series of school expenditure, including both government and private spending. Government expenditure is obtained from various official tabulations, and includes expenditure from all levels of government, provided to both public and private schools. Private expenditure is calculated from household expenditure surveys, from which we estimate private spending as a share of government spending. Taking account of changes in the share of children attending public and private schools, we then estimate private school spending in all years. Appendix 2 provides details of the derivation of our series.

One possible limitation to this estimate is that we are unable to disaggregate spending into primary and secondary school expenditure. Since per-pupil expenditure is typically higher for secondary school pupils than for primary school pupils, and since rising school completion rates mean that the share of pupils in secondary schools is higher in the early 2000s than in the mid-1960s, this will bias upwards the trend in school spending. Empirically, however, the extent of this bias is very small. In 2002-03, per-student spending in government schools was 28 percent higher at the secondary school level than at the primary school level (MCEETYA 2003, Appendix 1: Statistical annex, Table 20). Over the period spanned by our tests – 1975-98 and 1964-2003 – the share of pupils in secondary school grew by 4.6 and 4.4 percent respectively.¹⁷ This means that the upward bias to school spending caused by an increase in the share of students at the secondary school level was only 1.3 percent.

To adjust for price changes, we index the expenditure series in three ways. First, we adjust using the All Groups Consumer Price Index (CPI), which assumes that schools' input prices rose at the same price as other goods and services in the economy. Second, we construct a Schools Price Index (an index of the prices of inputs used by schools), to account for the possibility that the price of schools' inputs has been growing at a different rate from other prices. And third, we construct a price index based on the earnings of professional women, on the assumption that the largest expenditure item for schools is teacher salaries, and around 60-70 percent of teachers were women in this period.¹⁸

¹⁶ In their study of schooling productivity in OECD countries over the period 1970-94, Gundlach, Woessmann, and Gmelin used education expenditure data reported to the United Nations Educational, Scientific and Cultural Organization (UNESCO) (see the appendix to Gundlach, Woessmann, and Gmelin 1999).

¹⁷ An eagle-eyed reader may wonder at the fact that the secondary share grew more over the period 1975-98 than over the period 1964-2003. It is important to remember that the figure is not only affected by school completion rates (which have risen steadily), but also by cohort-specific factors, such as the baby boom.

¹⁸ To be precise, the share of teachers who were women was 67.4 percent in 2003, 65.9 percent in 1998, and 59.5 percent in 1975. This calculation includes both primary and secondary schools, and the government and non-government sector. We were unable to find the share in 1964, but the share of female teachers was 59.7 percent in 1970 and 55.0 percent in 1950. Linearly interpolating, this suggests that the share was 58.3 percent in 1964.

Panel A of Table 4 sets out the proportionate change in total school spending over time. Using the All Groups CPI, spending increased by 18 percent over the period of the LSAY, and by 333 percent over the period of the IEA tests. Using the Schools Price Index, spending increased by 10 percent over the period of the LSAY tests, and by 258 percent over the period of the IEA tests. Indexing schools' expenditure by the earnings of professional women, spending declined by 2 percent over the period of the LSAY, and rose by 76 percent over the period of the IEA tests. The substantially lower expenditure growth rates over the period spanning the LSAY data reflect the strong spike in per capita expenditure just prior to 1975, arising from school expenditure decisions made by the Whitlam Government on the advice of the Interim Committee (1973) report ("the Karmel report"). This spike is captured in the IEA growth rates, but not in the growth over the period spanned by the LSAY.

With all three price indices, real spending rose over the period of the IEA tests. Using two of the three price indices, real spending rose over the period of the LSAY tests. The exception is when spending is indexed by the earnings of professional women. This is consistent with Leigh and Ryan (2008), who find that – relative to professionals – new teachers' earnings declined from the mid-1970s to the mid-2000s.¹⁹ However, this index almost certainly overstates the expenditure that would have been necessary to keep pace with female professionals' wages (and therefore understates the rise in real spending). In 2002-03, teacher salaries comprised 63 percent of government school expenditure.²⁰ Even if one thought that teachers' salaries should have risen at the same rate as professional women's salaries, it would be more appropriate to take a weighted average of the All Groups price index and the Earnings of Professional Women price index. This approach implies a slightly lower rise than the Schools Price Index. (Using weights of 37 percent for the All Groups price index and 63 percent for the Earnings of Professional Women price index, this approach implies a 5 percent rise in real education expenditure between 1975 and 1998, and a 171 percent rise over the period from 1964 to 2003.)

Since we have more precise data on government expenditure than on private expenditure, Panel B of Table 4 replicates the results using only government expenditure. Over the periods covered by the LSAY and IEA tests, government expenditure on schools has risen substantially, though not as rapidly as private expenditure. Again, if expenditure is indexed by the earnings of professional women, we observe a decline over the period 1975-98. However, a weighted average of the All Groups price index and the Earnings of Professional Women price index still implies an increase in government school expenditure over this period.

Our preferred estimate uses both private and government expenditure, on the basis that our test scores are for children in both government and non-government schools. Our preferred price index is the Schools Price Index. We prefer the Schools Price Index to the All Groups Price Index since it allows for the cost of educational inputs to rise more rapidly than the prices of

¹⁹ The drop in teacher pay relative to other professionals is not confined to new teachers. A similar decline is also evident if one compares earnings for all teachers with those of all professionals (adjusted for the age composition of both groups). See Leigh and Ryan (2006, Appendix III).

²⁰ We calculate this figure using data in MCEETYA (2003, Appendix 1: Statistical annex, Table 19). Since the user cost of capital is not included in our estimates, we omit it when calculating the salary share of Australian government school expenditure.

other items in the economy. We also prefer it to the Earnings of Professional Women price index since the Schools Price Index does not make the unrealistic assumption that salaries constitute 100 percent of school expenditure. Using both private and government expenditure, indexed to the Schools Price Index, suggests that real per-child school expenditure increased by 10 percent over the period of the LSAY tests, and by 258 percent over the period of the IEA tests.

Where has the increased educational expenditure gone? One significant factor pushing up costs over this period has been smaller class sizes. In Appendix Table 5, we show student-teacher ratios for 1964-2004. On average, class sizes fell by 20 percent in the period 1975-98 and by 43 percent in the period 1964-2003. These patterns can be directly observed in our data: in the 1964 numeracy test, the average class size was 36, whereas in 2003, the average class size was 26.²¹

Assuming that salaries constitute 63 percent of all school spending, and that cutting class size requires a proportionate increase in funding, these cuts in class size would have boosted school spending by 13 percent over the period 1975-98, and by 27 percent over the period 1964-2003. Lower student-teacher ratios could therefore account for almost all of the expenditure increase over the period 1975-98, though not over the period 1964-2003.

One factor that might have increased expenditure without improving educational outcomes was the declining number of teachers in Catholic schools (and some independent schools) who were from religious orders, such as Brothers and Nuns. These teachers received a stipend that was less than the wage received by teachers in government schools at the time. As their numbers fell from the 1960s onwards, they were replaced by lay teachers who were paid a similar wage to government school teachers. (Or some cases, religious order teachers received a salary increase to put them on a similar footing to government school teachers.) Unfortunately, data on the gap between the stipend paid to religious teachers and the salary paid to lay teachers are limited.²² However, we do have data on the share of religious teachers in Catholic schools in various years.²³ Accounting for the share of students taught in Catholic schools, and assuming that wages constitute 63 percent of total expenditure, we can see how this factor would have affected total costs on the assumptions that the stipend was 25 percent, 50 percent, or 75 percent of a lay

²¹ Both the 1964 and 2003 IEA numeracy surveys contain data on average class size in the student's grade and school. While the bands are not directly comparable, they give some indication of the class size reduction over this period. In 1964, 7 percent of Australian students were in a class of 24 or fewer students, and 70 percent of students were in a classroom with 35 or more students. In 2003, 31 percent of students were in a class of 24 or fewer students, and 4 percent were in a class of 33 or more students. There is no systematic relationship in either survey between test scores and class size, though it is quite possible that non-random sorting might offset causal impacts in either direction.

²² The only estimate we were able to obtain was from the South Australian Catholic Education Office, which informed us that their current religious stipend equates to 62 percent of the average salary paid to Australian school teachers. We are grateful to Geoff Hallion of Catholic Education South Australia for providing us with this information.

²³ Flynn and Mok (2002) provide data on the share of Catholic teachers from religious orders in 1965 (72.3 percent), 1971 (47.8 percent), 1993 (4.0 percent), and 2000 (1.6 percent). We linearly interpolate and extrapolate to obtain estimates for the years 1964, 1975, 1998, and 2003.

teacher's salary.²⁴ From 1964-2003, the increase in spending caused by the shift from religious to lay teachers would have led to a 7 percent spending increase if the stipend for religious teachers was 25 percent of lay salaries, 5 percent if the stipend was 50 percent of lay salaries, and 2 percent if the stipend was 75 percent of lay salaries. Over the period 1975-1998, the impact on total spending would have been 4 percent, 3 percent, and 1 percent respectively. While this is clearly non-trivial, the movement away from religious teachers in Catholic schools can only account for a small share of the full increase in spending over either period.

One way of estimating the change in productivity of Australian schools is to divide the test score trends by the expenditure trends. In effect, this exercise estimates the necessary expenditure required for each point on the literacy and numeracy tests. We find that school productivity has declined by 12-13 percent between 1975 and 1998, and by 73 percent between 1964 and 2003.²⁵ This contrasts starkly with multifactor productivity across the economy, which rose by 34 percent in the period 1975-98, and by 64 percent in the period 1964-2003 (ABS 2006).

V. Discussion and Conclusion

Depending on which measure we employ, the test scores of young Australian teenagers appear to have fallen slightly from the mid-1960s to the early 2000s. Although our confidence intervals in some cases include zero, we can reject the hypothesis that there has been a statistically significant increase in test scores over the past four decades. While we do not have as full a set of demographics as we would like, adjusting test scores to account for changes in the available demographic characteristics does not explain the decline; rather, the decline seems even larger. The results are economically significant, implying a drop of between one-fifth and one-tenth of a standard deviation. This suggests, for example, that the numeracy of the typical young teenage student in 2003 was approximately a quarter of a grade level behind his or her counterpart in 1964. This drop contrasts with the U.S., where standardized test scores merely flatlined from the 1970s to the 1990s (Hanushek 1997; Hoxby 2001).

Turning to expenditure data, our preferred estimate is that real per-child school expenditure increased by 10 percent over the period of the LSAY tests (1975-98), and by 258 percent over the period of the IEA tests (1964-2003). These results are not particularly sensitive to the exclusion of private expenditure, or the use of other reasonable price indices. Dividing the test score trends by the expenditure trends suggests that school productivity declined by 12-13 percent over the period covered by the LSAY tests and by 73 percent over the period covered by the IEA tests. This is consistent with results from other developed nations, and suggests that resources alone are not the answer to improving school performance. Instead, education

²⁴ The share of students in Catholic schools in our years of interest was 19.6 percent (1964), 17.0 percent (1975), 19.7 percent (1998), and 19.9 percent (2003). Our estimates account for changes in the 'market share' of Catholic schools.

²⁵ An alternative (narrower) measure of the increase in school inputs would be the reduction in student-teacher ratios, which fell by 20 percent over the period 1975-98, and by 43 percent over the period 1964-2003 (Appendix Table 5). If this were regarded as the only input, it would imply a reduction of school productivity in the order of 19-20 percent between 1975 and 1998, and a reduction of 32 percent between 1964 and 2003.

policymakers should rigorously evaluate the impact of new reforms, and focus on raising the quality of education expenditure.

Although we have done our best to adjust our results given the data available to us, we cannot fully rule out explanations that have nothing to do with school productivity. For example, it is plausible that changing family structure, social norms, and entertainment media may have affected test scores. Alternatively, it might be the case that our measure of school outputs is unduly narrow, and fails to capture factors that do not appear on our tests – such as physical fitness, critical thinking skills, problem solving skills, communication skills, or knowledge of science. Since we do not have data on these other outputs, it is not possible to know whether they have risen or fallen over time.

However, it is possible to identify explanations that relate directly to school productivity. First, part of the spending increase over the period in question resulted from class size cuts. If smaller classes have little or no impact on test scores (Hanushek 1998; Hoxby 2000; Rockoff 2009; but cf. Krueger 1999, 2003), then this policy change would have led to a reduction in school productivity. A second possibility is that falling teacher quality led to a disproportionate drop in student performance. If a 10 percent reduction in real teacher salaries reduces student performance by more than 10 percent, then falling teacher salaries could lower school productivity. A third productivity-related explanation is that shifts in the way that schools were managed led to a decline in school productivity. For example, Australian universities and teachers' colleges shifted towards a whole-language approach to teaching reading in the 1970s (van Kraayenoord and Paris 1994). To the extent that this was less effective than other methods of reading instruction, it might also have led to a decline in school productivity.²⁶ Although our approach does not allow us to distinguish between these explanations, we hope it will encourage further analysis.

²⁶ Similarly, it is possible that the mainstreaming of students with disabilities reduced mean test scores. This might occur for two reasons. The first is if the positive peer effects for disabled students were lower than the negative peer effects for non-disabled students. We are not aware of any research that bears directly on this issue. The second is if a significant proportion of very low-scoring students were added to the group sitting the tests. None of the individual distributions in Figures 3 and 5 show such an addition. Rather, the decline in performance occurred across the entire distributions.

Figure 1: Literacy (LSAY)

Note: Sample is 14 year-olds in grade 9. Capped spikes depict 95% confidence interval for mean.

Figure 2: Numeracy (LSAY)

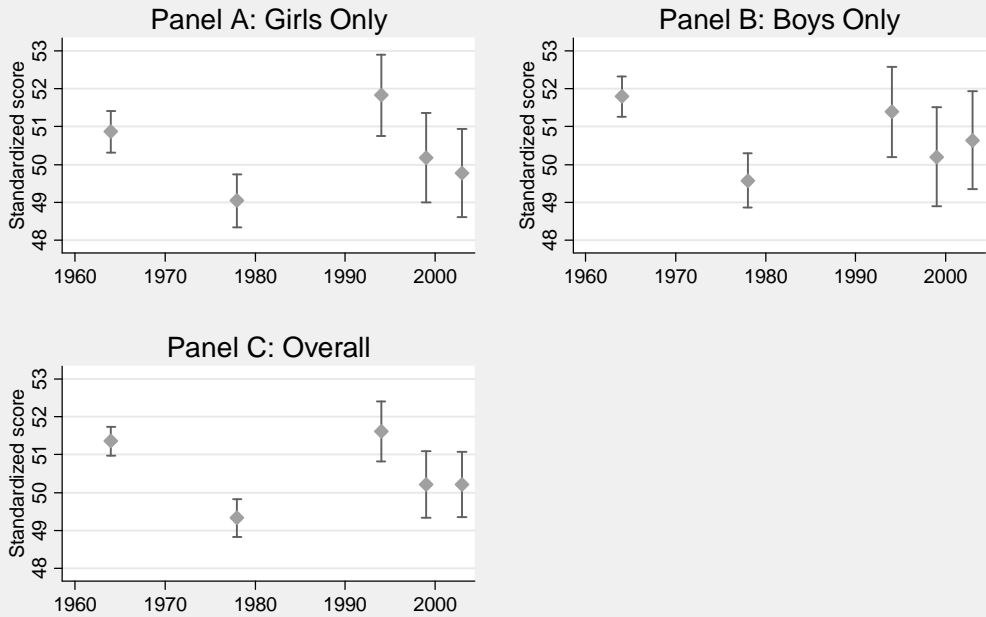

Note: Sample is 14 year-olds in grade 9. Capped spikes depict 95% confidence interval for mean.

Figure 3: Distributions (LSAY)

Note: Sample is 14 year-olds in grade 9. Continuous line represents 1975, dashed line represents 1998.

Figure 4: Numeracy (IEA)

Note: Effects are adjusted for student age and grade. Capped spikes depict 95% confidence interval for mean.

Figure 5: Distributions (IEA)

Note: Effects are adjusted for student age and grade. Continuous line represents 1964, dashed line represents 2003.

Table 1: Long-Run Test Score Changes in Australia

Age	Test	Period	Total Change (LSAY scale)	Total Change (IQ scale)	Years	Change per year (IQ scale)
Panel A: Flynn Findings (1936-81)						
10-14	Jenkins	1949-81	10.45	15.67	32	0.490
10-16	Ravens	1950-76	5.84	8.76	26	0.337
10-14	Otis	1936-49	3.67	5.50	13	0.423
Panel B: Trends in School Tests (1964-2003)						
14	LSAY Literacy	1975-98	-2.07	-3.10	23	-0.135
14	LSAY Numeracy	1975-98	-1.67	-2.50	23	-0.109
13	IEA Numeracy	1964-2003	-1.14	-1.71	39	-0.044

Source: Panel A is from Flynn (1987). Panel B is from authors' calculations. The LSAY scale has a standard deviation of 10. The IQ scale has a standard deviation of 15. All changes are statistically significant at the 5 percent level or better.

Table 2: Decomposition of Changes in Test Scores

	(1) LSAY Literacy (1975 to 1998)	(2) LSAY Numeracy (1975 to 1998)	(3) IEA Numeracy (1964 to 2003)
Change in average test score (all students in sample)	-2.07	-1.67	-1.14
<u>Decomposition</u>			
Change in average test score (students with non-missing demographics)	-1.00	-0.58	-0.90
<u>Earlier year as base</u>			
Change attributable to levels of student demographics	+1.44	+1.92	+3.64
Change attributable to returns to student demographics	+0.98	+1.36	+3.02
Change not attributable to observed demographics	-3.42	-3.86	-7.56
<u>Later year as base</u>			
Change attributable to levels of student demographics	+1.21	+1.19	+3.81
Change attributable to returns to student demographics	+1.21	+2.09	+2.85
Change not attributable to observed demographics	-3.42	-3.86	-7.56

Note: LSAY: Sample is 14 year-olds in grade 9, and demographics are indicators for student gender, whether the school is in a metropolitan area, whether it is a Catholic school, whether it is an Independent school, whether the student was born in a non-English-speaking country, whether the student's mother was born in a non-English-speaking country, the share of students in the school with a mother born in a non-English-speaking country, the number of siblings that the student has, whether the student's father has a degree, whether the student's mother has a degree, parents' occupational status (on the ANU 3 scale), and indicators for each state and territory. IEA: Test scores are the residual from a regression of the Rasch score on indicators for age and grade. Demographics are student gender, an indicator for whether the student/school is in a metropolitan area, and indicators for whether the student's mother and father have lower secondary education, upper secondary education, a trade qualification, or a university degree.

Table 3: Effect of Social Factors on Numeracy Performance (2003)

	(1)	(2)
Likes school (indicator) <i>Mean=74%</i>	1.924 [0.458]	1.041 [0.444]
Bullied (indicator) <i>Mean=27%</i>	-0.325 [0.462]	-0.267 [0.441]
TV watching (hours per day) <i>Mean=1.96 hours</i>	-0.840 [0.168]	-0.549 [0.165]
Student age and gender controls	Yes	Yes
Parental SES controls	No	Yes
Observations	3683	3683
R-squared	0.05	0.15
Predicted impact on scores if:		
- All children like school	+0.500	+0.271
- No children are bullied	+0.088	+0.072
- No children watch TV	+1.646	+1.076
- All of the above	+2.234	+1.419

Note: Robust standard errors in brackets. Both regressions include indicators for student gender and student age (in months). Parental SES controls are whether the school is in a metropolitan area, and includes indicators for the number of books in the home, the number of people in the home, how often English is spoken at home, mother and father's educational attainment, and whether the mother and father were born overseas. Sample is respondents from the Australian wave of the 2003 IEA, with non-missing demographics.

Table 4: Increase in Schools Expenditure (percent)*Preferred estimates in bold text*

Year	Nominal Spending per Child	Indexed by All Groups Price Index	Indexed by Schools Price Index	Indexed by Earnings of Professional Women
Panel A: Private and Government Expenditure				
1997-98	429%	18%	10%	-2%
1974-75				
2002-03	4,147%	333%	258%	76%
1963-64				
Panel B: Government Expenditure Only				
1997-98	410%	14%	6%	-5%
1974-75				
2002-03	3,962%	314%	243%	69%
1963-64				

Appendix 1: Common Questions Across IEA Numeracy Tests

Below, we show some examples of the common questions used on the IEA tests. In comparing results, readers should bear in mind that the age and grade level differed across tests (see text for details).

- (i) In the division $24.56/0.04$, the correct answer is
a. *0.614* b. *6.14* c. *61.4* *d. *614* e. *6140*

Fraction correct - 1964: 39%; 1978: 38%; 1995: 23%.

- (ii) Joe had three test scores of 78, 76, and 74, while Mary had scores of 72, 82, and 74. How did Joe's average compare with Mary's?
a. *Joe's was 1 point higher.*
b. *Joe's was 1 point lower.*
*c. *Both averages were the same*
d. *Joe's was 2 points higher.*
e. *Joe's was 2 points lower.*

Fraction correct - 1964: 88%; 1978: 83%; 1995: 74%; 1999: 74%; 2003: 68%.

- (iii) If $P=LW$ and if $P=12$ and $L=3$, then W is equal to
a. *3/4* b. *3* *c. *4* d. *12* e. *36*

Fraction correct - 1964: 68%; 1978: 63%; 1995: 66%.

- (iv) If $x/2 < 7$, then
a. *$x < 7/2$* b. *$x < 5$* *c. *$x < 14$* d. *$x > 5$* e. *$x > 14$*

Fraction correct - 1964: 37%; 1978: 38%; 1995: 41%.

- (v) Which of the following is false when a and b are different real numbers:
a. *$(a+b) + c = a + (b+c)$*
b. *$ab=ba$*
c. *$a+b=b+a$*
d. *$(ab)c=a(bc)$*
e. *$a-b=b-a$* *

Fraction correct - 1964: 41%; 1978: 46%; 1995: 33%.

(vi) If AB is a straight line, what is the measure in degrees of the angle BCD in the figure?

- a. 20 b. 60 c. 50 *d. 80 e. 100

Fraction correct - 1964: 62%; 1978: 60%; 1995: 75%.

(vii) If $x = -3$, the value of $-3x$ is

- a. -9 b. -6 c. -1 d. 1 *e. 9

Fraction correct - 1964: 29%; 1978: 37%; 1995: 38%; 1999: 52%.

(viii) A runner runs 3,000 metres in exactly 8 minutes. What was his average speed, in metres per second?

- a. 3.75. *b. 6.25 c. 16.0. d. 37.5. e. 62.5

Fraction correct - 1964: 47%; 1978: 28%; 1995: 28%; 1999: 30%.

(ix) If, in the given figure, PQ and RS are intersecting straight lines, then $x+y$ is equal to

- a. 15. b. 30. *c. 60. d. 180 e. 300

Fraction correct - 1964: 41%; 1978: 32%; 1995: 51%; 1999: 55%; 2003: 50%.

Appendix 2: Expenditure on Primary and Secondary Education

Government Expenditure

Our total expenditure series is created as follows:

- 1963-64 to 1979-80: We use data on expenditure on education published by the Commonwealth Bureau of Census and Education (the publication that subsequently became *Expenditure on Education, Australia*, ABS Cat No 5510.0). Our series sums expenditure by state and federal government on primary and secondary schools. For 1963-64 to 1967-68, federal expenditure on schools is not separately tabulated, so we use total expenditure on education.
- 1980-81 to 1997-98: We use data from *Expenditure on Education, Australia*, ABS Cat No 5510.0.
- 1998-99 to 2003-04: We use data on operating expenses on primary and secondary education, from *Government Finance Statistics, Education*, ABS Cat No 5518.0.

In recent years, school expenditure series have also included a notional user cost of capital. Since that information is not available for earlier years, we do not include it in our series.

Student enrolment data are obtained from the *Australian Yearbooks* (various years).

Private Expenditure

We are not aware of any consistent series of private expenditure on schools. Our calculations are therefore based on data from the *Household Expenditure Survey* (HES). In the years 1984, 1988-89, 1993-94, and 1998-99, the HES contains comparable data on school fees, tabulated by primary/secondary and government/non-government schools (figures from the 1974 and 2003-04 HESs were not directly comparable).

Using data on the number of students enrolled in each of these categories (from the *Australian Yearbooks*), and the number of households in Australia (from *Australian Demographic Statistics*, ABS Cat No 3101.0), we estimate the average annual expenditure per student in the following categories: government primary, government secondary, non-government primary, non-government secondary. We then calculate the ratio of fees to government expenditure in each of these years. In three of the HESs (1984, 1988-89, and 1998-99), the ratios are very similar. However, in the 1993-94 HES, the ratio of private school fees to government expenditure differs significantly from the other surveys, so we opt not to use this year. The ratio of private spending to government spending is listed in Appendix Table 1.

We estimate per-student private expenditure for all years by combining the estimates in Appendix Table 1 with data on the share of students in each of the four types of schools (government primary, government secondary, non-government primary, non-government secondary), and with government expenditure per student.

Our nominal expenditure series are presented in Appendix Table 2.

Price Indices

We use three price indices to adjust the expenditure series.

1. The All Groups CPI is simply obtained from *Consumer Price Index, Australia*, ABS Cat No 6401.0.
2. We construct a Schools Price Index, by splicing together the following series:
 - 1963-64 to 1965-66: Miscellaneous Groups CPI, from ABS CPI, Cat No 6401.0.
 - 1966-67 to 1977-78: Other Services CPI, from Clements and Izan (1985).
 - 1978-79 to 1992-93: Schools Prices Index, from the Statistical Annex to the *National Report on Schooling in Australia* (various years) prepared by the Department of Education, Science and Training.
 - 1993-94 to 2003-04: Education CPI, from ABS CPI, Cat No 6401.0.
3. We construct a price index based on the earnings of female professionals. This is based on the assumption that the main expenditure item for schools are teacher salaries, and that the education sector must compete against other professional occupations. Our index splices together the following series:
 - 1963-64 to 1974-75: Based upon an index of women's award wages, constructed by Snooks (1994).
 - 1975-76 to 2003-04: Based upon the average weekly ordinary time earnings for full-time female professionals, from the *Employee Earnings and Hours* survey.Note that the index is very similar if we use the earnings of all female workers instead of professionals.

Where price indices were reported quarterly, we calculate an annual average.

While the Australian financial year runs from July to June, some of our series are only available on a calendar year basis. In these instances, we match to the second half of the financial year (e.g. *Employee Earnings and Hours* data for 1976 are used to construct the female professionals' earnings index in the financial year 1975-76).

The three price indices are presented in Appendix Table 3. The three real expenditure series are presented in Appendix Table 4.

Student-Teacher Ratios

Student-teacher ratios are estimated from the following sources:

- 1964-75: We combine data on the number of teachers and students, sourced from the respective *Australian Yearbooks*.
- 1976-2001: Sourced from *Education and Training Indicators, Australia, 2002*, ABS Cat No 4230.0, Data Cubes Topic 11.
- 2002-2004: Sourced from *Schools, Australia*, ABS Cat No 4221.0, Table 54.

Student-teacher ratios are presented in Appendix Table 5.

Appendix Table 1: Ratio of Private Expenditure to Government Expenditure

HES Year	Govt Primary	Govt Secondary	Non-Govt Primary	Non-Govt Secondary	Used for years
1984	1.1%	3.3%	21.8%	62.9%	1963-64 to 1987-88
1988-89	1.4%	3.8%	20.6%	62.9%	1988-89 to 1997-98
1993-94	1.4%	5.2%	20.1%	76.1%	Not used
1998-99	1.4%	4.2%	25.8%	62.7%	1998-99 onward

**Appendix Table 2: Nominal Education Expenditure
(Spending per child per year, in current dollars)**

Year	Government Spending	Private Spending	Total Spending
1963-1964	\$165	\$18	\$183
1964-1965	\$178	\$19	\$197
1965-1966	\$188	\$20	\$208
1966-1967	\$201	\$21	\$222
1967-1968	\$221	\$23	\$244
1968-1969	\$247	\$30	\$277
1969-1970	\$281	\$28	\$309
1970-1971	\$327	\$32	\$359
1971-1972	\$382	\$37	\$419
1972-1973	\$444	\$44	\$488
1973-1974	\$573	\$57	\$630
1974-1975	\$899	\$89	\$987
1975-1976	\$1,074	\$106	\$1,180
1976-1977	\$1,200	\$118	\$1,318
1977-1978	\$1,367	\$135	\$1,502
1978-1979	\$1,449	\$146	\$1,595
1979-1980	\$1,570	\$162	\$1,732
1980-1981	\$1,525	\$162	\$1,687
1981-1982	\$1,713	\$189	\$1,901
1982-1983	\$2,000	\$228	\$2,228
1983-1984	\$2,193	\$259	\$2,452
1984-1985	\$2,442	\$298	\$2,740
1985-1986	\$2,597	\$325	\$2,922

1972-1973	\$3,433	\$3,804	\$5,316
1973-1974	\$3,915	\$4,538	\$4,870
1974-1975	\$5,267	\$6,429	\$6,439
1975-1976	\$5,568	\$5,992	\$6,672
1976-1977	\$5,467	\$6,162	\$6,601
1977-1978	\$5,686	\$6,963	\$6,944
1978-1979	\$5,584	\$6,930	\$6,911
1979-1980	\$5,498	\$7,058	\$6,729
1980-1981	\$4,900	\$6,215	\$5,866
1981-1982	\$4,997	\$6,271	\$5,861
1982-1983	\$5,249	\$6,348	\$6,167
1983-1984	\$5,413	\$6,629	\$6,352
1984-1985	\$5,800	\$6,987	\$6,669
1985-1986	\$5,705	\$7,158	\$6,191
1986-1987	\$5,512	\$7,168	\$6,400
1987-1988	\$5,313	\$7,143	\$6,189
1988-1989	\$5,494	\$7,509	\$6,435
1989-1990	\$5,293	\$7,346	\$6,385
1990-1991	\$5,404	\$7,402	\$6,446
1991-1992	\$5,656	\$7,467	\$6,476
1992-1993	\$5,738	\$7,480	\$6,434
1993-1994	\$5,740	\$7,332	\$6,234
1994-1995	\$5,694	\$7,214	\$6,159
1995-1996	\$5,753	\$7,228	\$6,348
1996-1997	\$5,935	\$7,122	\$6,316
1997-1998	\$6,231	\$7,044	\$6,326
1998-1999	\$7,248	\$7,895	\$7,257
1999-2000	\$7,478	\$7,955	\$7,472
2000-2001	\$7,470	\$8,029	\$7,658

**Appendix Table 4: Real Education Expenditure
(Spending per child per year, in 2003-04 dollars)**

2001-2002	\$7,686	\$8,133	\$7,851
2002-2003	\$7,961	\$8,271	\$8,070
2003-2004	\$8,297	\$8,297	\$8,297

Appendix Table 5: Student-Teacher Ratio

Year	Student-Teacher Ratio	Year	Student-Teacher Ratio
1964	25.4	1985	15.2
1965	25.0	1986	15.3
1966	25.6	1987	15.1
1967	25.1	1988	15.1
1968	24.3	1989	15.3
1969	23.8	1990	15.3
1970	23.1	1991	15.4
1971	22.6	1992	15.3
1972	21.8	1993	15.3
1973	21.0	1994	15.5
1974	20.2	1995	15.4
1975	19.2	1996	15.4
1976	18.6	1997	15.3
1977	18.0	1998	15.3
1978	17.6	1999	15.0
1979	17.0	2000	14.9
1980	16.9	2001	14.7
1981	16.8	2002	14.7
1982	16.5	2003	14.5
1983	16.1	2004	14.3
1984	15.6		

Proportionate change in class size from:

1975 to 1998	-20%
1964 to 2003	-43%

Impact of class size reduction on spending (assuming salaries constitute 63% of total school expenditure)

1975 to 1998	+13%
1964 to 2003	+27%
